Abstract

Riparian zone is the area adjoining the river and includes the river bank. This zone has high relevance and plays an important role in the river ecosystem. The present study was undertaken to understand the distribution of the avian diversity along the riparian zone and related the same with the landscape. The study was undertaken in river Vishwamitri flowing through the Vadodara city covering a distance of 90 Km before draining into the Arabian Sea. The paper reveals that there are about 69 species distributed all along the lengths of the river and the distribution is governed by the land use pattern like agriculture or urban area. Alteration of the riparian zone by human interventions would disturb the natural habitat and result in decline of diversity.

Keywords: riparian zone, avifauna, abundance

Introduction

Riparian zones are long and thin, and consequently have an extensive interface with adjacent ecosystems. Its defined as an ecological complex, is all land directly adjacent to a watercourse includes flood plains and wetlands (Parsons, 1991; Walker, 1993). The role of riparian areas as corridors has become increasingly important as surrounding ecosystems are modified for urban and agricultural purposes. The riparian land act as buffering zone and protects aquatic environments against erosive or polluting land uses. Home ranges of many animals include areas of both the riparian zone and adjacent habitats, and so habitat modification to either area will affect these species. Many riparian zones are now characterized by the loss of linear and upslope connectivity. The importance of riparian vegetation for wildlife habitat has been shown in a number of studies (Crome *et al.*, 1994; Fisher and Goldney, 1997; Recher and Lim, 1990) [4]. Vegetation with a complex structure like herb, shrub and tree layers which often occurs in the riparian zone is important nesting and foraging habitat for many bird species. Some water-birds such as herons, rails and bitterns and warblers use thick reed beds and other vegetation fringing watercourses. The riparian zone provides food for all trophic levels of the food web, starting with microbes to top consumers. The extensive ecotone is intrinsically linked to the surrounding catchment through material flows like water, soil, nutrients, chemicals and animal movement (Naiman and Décamps, 1997).

Threats to the terrestrial or aquatic birds of the riparian zone stem are largely from habitat fragmentation and removal or modification of riparian zone itself or arising adjacent ecosystems. Other threats include urbanization, changes in water quality or flows, increased predation from introduced predators, and human disturbance.

Vishwamitri river is a small river with a span of 90 km before merging with the Dhaddhar river and finally into the Arabian Sea. The river is known to harness Schedule IV species like fresh water marsh crocodiles, fresh water turtle and about 77 bird species (Dhuru, 2002) [8]. Majority of the bird species seen are resident, however, a few species of migratory birds such as the

wagtails, Rosy pastor, sandpipers, snipes etc have also been sighted (Dhuru, 2002) [8]. The river passes through Vadodara city and about 14 km of the stretch falls within the urban area.

Study Area

The total length of the river is about approximately 90 Km. It flows for 58Km through Vadodara district and 13 km through Vadodara city, dividing the city into Northern and Southern Part (Gujarat Engineering Research Institute (GERI, 2014). Considering the short length of the river ten sampling stations were selected in such a manner that six stations were in the clean zone of the river, three in the septic zone and one in the recovery zone. As far as possible equal distance (average 9 Km distance occur between each two points) was maintained between all the stations.

Methodology

Satellite Imagery Data (Google Earth) was use in order to demarcate and total of 10 sites recognized and survey conducted in the month of January and February. Survey was carried out early in the morning from 8: 00 to 10: 30 h using line transect or point transects (point count) method. Birds was observed using binoculars (10*50). The species was identified using recognized field guides (Grimmett *et al.* 2006).

Data was collated and various indices calculated like relative abundance, Species richness, Shannon-Weiner's diversity index, Species evenness index and Jaccard's similarity index.

Result and Discussion

Although entire riparian zone of Vishwamitri river was dominated by residential and terrestrial birds, but it also provide habitat to winter visitor and aquatic birds. Based on major feeding habit, riparian zone was highly visited by insectivorous birds followed by Carnivorous, Granivorous, Omnivorous, Frugivorous and Nectarivorous.

Relative abundance (%) of all the birds species was calculated where in the abundance of top five species in each study area was considered.

At study area 1 and 10, jungle babbler (*Turdoides striata*), an insectivore bird showed high relative abundance as compared to other birds species. Both the areas are away from the urban influence and studies indicate that the richness of insectivores bird species declines with increase in built up area and close to human habitation (Lim and Sodhi, 2004) [23]. Study area 2 showed the dominance of Asian Palm Swift (*Cypsiurus balasiensis*) attributed to presence of palm trees which provides apt habitat for the species (Koladia, 2014). Rock Dove (*Columba livia*) showed high relative abundance at study area 3 supported by the thick vegetation that provide food and nesting material (Wely and Baptista, 1988) [41].

At study area 4, Bank Myna (*Acridotheres ginginianus*) had the highest relative abundance. It has a close association with man-made habitats and regularly enters cities and agricultural lands (Elliot, 2009). Large billed crow (*Corvus macrorhynchos*) shared similar relative abundance at study area 5 compared to other areas. Dense woody vegetation as well as food waste dumped by villager near the riparian zone makes the site prominently visited by this omnivorous bird. Thus, Omnivorous species has adapted to the semi urban environment and its particular food resources such as garbage (Clergeau *et al.* 1998) [6]. At study area 6, Common Myna (*Acridotheres tristis*) had the highest relative abundance. A bold and aggressive bird has a close association with human habitation. It naturally occurs in open country, such as cultivated areas, floodplains and grasslands, but is now most abundant in towns and cities found around parks, gardens and refuse dumps (Sargatal, 2009).

Study area 7 had Rose-ringed parakeets (*Psittacula krameri*) as highest relatively occurring bird. Sparse vegetation in the bank and high human disturbance supported this species.

Incidentally at study area 8, Black headed ibis (*Threskiornis melanocephalus*) showed high relative density. This area has presence large woody trees like ficus species, acacia species, etc. that provide roosting and breeding grounds to the dominative species (Munjpara, 2012) [28]. At study area 9, cattle egret (*Bubulcus ibis*) showed the highest relative density. Dense bushy vegetation of *Prosopis juliflora* and presence of high insect density in the area provided the apt habitat for this species (Munjpara, 2012) [28].

On the distribution of the water birds a difference was observed among all the study area. Study area 1 and 5 showed the highest relative abundance of Red-wattled lapwing (*Vanellus indicus*). This indicates presence of worms, molluscs, amphibians and other invertebrates on which the bird feeds (Elliott, 1996). At the Study area 3, Grey wagtail (*Motacilla cinerea*) and Red-wattled lapwing share same relative abundance. Again this indicates the presence of insect's availability (Birdguide, 2011).

At the Study area 4 relative abundance of Glossy ibis (*Plegadis falcinellus*) was high, attributed to presence of irrigated agricultural fields that provides food like adults and larvae of various insects, molluscs, crustaceans (Sargatal, 1992). In case of Study area 7, relative abundance of Black-winged stilt

(*Himantopus himantopus*) was high. It's bio-indicator species feeding on mosquito larvae that thrive in the water with high organic content (Khachar, 1994). At Study area 8, abundance of Black-headed ibis was found to be high as this species sometimes nest close to human dwellings if relatively undisturbed (Kahl, 1992).

Further, at study area 9, highest relative abundance was scored by Common Sandpiper (*Actitis hypoleucos*). In its winter range, this species occurs in a wide variety of habitats, from coastal shores to inland wetlands, riverbanks and even sewage works (Yalden, 1986). At Study area 10, relative abundance of Indian Pond-heron (*Ardeola grayii*) was high. This species was found to be more tolerant towards water pollution and human disturbances because omnivorous species do exploit anthropogenic food resources effectively (Jokimaki and Suhonen, 1998).

Munjmahuda had highest species richness. This zone supported both terrestrial and aquatic birds. Dense scrub vegetation and nutrient rich water helped to sustain avian-fauna. Urban exploiters like Rock doves were plenty in number. Asoj and Dena had least numbers of species richness, irrespective of dense vegetation. High human disturbance have affected the species richness at this site.

In the case of species diversity, area 2 and 9 showed comparatively high diversity. Though being distantly apart, both the areas had almost similar vegetation characteristics, high tree density, low human disturbance.

Highest species evenness was found at area 6, because the population of individual bird species was similar and ranged from 1 to 5. Area 5 showed the low evenness score, because of high population (> 20) of few species.

Similarity index is high between study area 9 and 4 related presence of dense vegetation, food availability and nesting ground for birds. The old heritage type of buildings provide the suitable habitat for nesting to House Swifts and therefore their density is high (Rathod, 2009). The amount of shrub cover is also principal microhabitat characteristic that increases bird's tolerance to people in urban areas (Fernandez-J *et al.*, 2001). Study area in close proximity like 7 and 8, 4 and 5 had same similarity index. The continuity of vegetation and other habitat in small distances is one of the reasons for the same similarity index. Degradation of riparian lands due to growth of slums, mining of river banks, overgrazing, dumping of domestic and health hazardous waste, removal or fragmentation of native vegetation, etc. will affect the riparian sensitive species (Geier & Best 1980, Pearce *et al.* 1994).

The study has immense potential to show case the varied diversity present along the river course and gains importance when the city is planning for river front. Clearing of native woody riparian vegetation will result in the replacement of a diverse wildlife community composed of species that are typically found in riparian forest or woodland by a different, often less diverse (Wardell-Johnson & Roberts 1991).

Conclusion

The study conducted along the riparian zone of Vishwamitri river concludes that, the river and the riparian zone together support a good diversity of bird species. The varied vegetation characteristics along the river influenced the high bird diversity reported here. The results of the present study form a comprehensive baseline data to assess and correlate the faunal diversity with its associated habitat. Any form of manmade intervention to the riverine system will affect the bird diversity and associated other wildlife species. There is need to restore the riparian vegetation in the areas where the vegetation is cleared for pasture or agriculture.

Acknowledgment

I kindly thank Prof. Arun Arya, The Maharaja Sayajirao University and Dr. Deepa Gavali, Gujarat Ecology Society for their valuable comments, suggestions and resources. I also thank other member of Gujarat Ecology Society for their assistance in the field.
